**Glioblastoma, the most common malignant brain tumor, is among the most lethal and difficult cancers to treat. Although epidermal growth factor receptor (EGFR) mutations are frequent in glioblastoma, their clinical relevance is poorly understood. Studies of tumors from patients treated with the EGFR inhibitor lapatinib revealed that EGFR induces the cleavage and nuclear translocation of the master transcriptional regulator of fatty acid synthesis, sterol regulatory element-binding protein 1 (SREBP-1). This response was mediated by Akt; however, clinical data from rapamycin-treated patients showed that SREBP-1 activation was independent of the mammalian target of rapamycin complex 1, possibly explaining rapamycin's poor efficacy in the treatment of such tumors. Glioblastomas without constitutively active EGFR signaling were resistant to inhibition of fatty acid synthesis, whereas introduction of a constitutively active mutant form of EGFR, EGFRvIII, sensitized tumor xenografts in mice to cell death, which was augmented by the hydroxymethylglutaryl coenzyme A reductase inhibitor atorvastatin. These results identify a previously undescribed EGFR-mediated prosurvival metabolic pathway and suggest new therapeutic approaches to treating EGFR-activated glioblastomas.**

## INTRODUCTION

Glioblastomas (GBMs) aggressively invade the surrounding brain, making complete surgical excision impossible. Unfortunately, GBMs are also among the most radiation- and chemotherapy-resistant of all cancers. On average, GBM patients survive 12 to 15 months from the time of initial diagnosis (1, 2). The epidermal growth factor receptor (EGFR), which is amplified in up to 45% of GBM patients (3), has oncogenic activity (4, 5). However, EGFR inhibitors have been ineffective in the clinic (6). Maintenance of signal flux through the phosphatidylinositol 3-kinase (PI3K)–Akt–mammalian target of rapamycin complex 1 (mTORC1) pathway, either as a consequence of PTEN (phosphatase and tension homolog deleted from

chromosome 10) loss (7, 8), a key negative regulator of PI3K signaling, or through coactivation of other receptor tyrosine kinases (RTKs) (9), together with failure to block EGFR-mediated changes in cellular metabolism, have been suggested as possible explanations for the resistance of multiple cancers, including GBMs, to inhibitors of EGFR tyrosine kinase activity (10–13). However, attempts to determine the clinical importance of EGFR signaling in GBM have been hampered by a lack of studies designed to assess the short-term effects of EGFR inhibitors on signal transduction and tumor metabolism in patients. Here, we analyzed GBM clinical samples, cell lines, and a mouse model to identify an EGFR- and Akt-dependent, rapamycin-insensitive signaling pathway that promotes GBM cell survival through sterol regulatory element-binding protein 1 (SREBP-1)–dependent fatty acid synthesis.

## RESULTS

### Inhibition of EGFR-PI3K-Akt signaling suppresses SREBP-1 nuclear translocation in GBM patients treated with lapatinib

As part of a Phase II clinical trial for the EGFR inhibitor lapatinib, we performed quantitative immunohistochemical analysis of tumor tissue from the first nine GBM patients for whom tissue was available both at initial diagnosis (surgery 1) and after a 7- to 10-day course of treatment (surgery 2) (Fig. 1A). We have previously demonstrated the effectiveness of this assay in measuring drug-specific effects in GBM patients (14). Access to pre- and posttreatment samples for each patient facilitated intrapatient comparison of molecular endpoints, enhancing the

statistical power to detect changes in this small sample size. Immunohistochemical staining for EGFR phosphorylated on Tyr<sup>1086</sup> (p-EGFR), a measure of EGFR activation (Fig. 1, B and C), was significantly decreased in tumors from lapatinib-treated patients ( $P < 0.05$ ). Decreased p-EGFR was detected in tumors from six of nine patients (Fig. 1D), with increased intratumor lapatinib concentration in tumors that demonstrated decreased EGFR phosphorylation (table S1). Staining for Akt phosphorylated on

Ser<sup>473</sup> (p-Akt), a measure of PI3K pathway activity (15), was also significantly decreased after lapatinib treatment ( $P < 0.01$ ) (Fig. 1, B and C), consistent with the decrease in p-EGFR ( $P < 0.01$ ) (Fig. 1D). Thus, lapatinib inhibited EGFR signaling through Akt in GBMs from most patients examined.

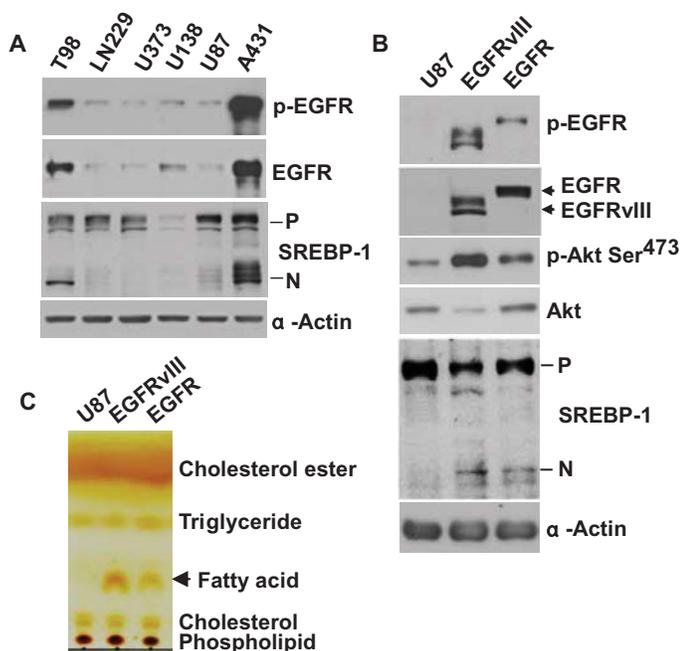

PI3K signaling is associated with increased fatty acid synthesis (16); therefore, we examined the effect of lapatinib on SREBP-1, the master

**Fig. 1.** EGFR and Akt signaling and nuclear SREBP-1 accumulation response data in the first set of nine GBM patients receiving lapatinib in a Phase II clinical trial. (A) Tumor tissue was analyzed from nine GBM patients before and after treatment with the EGFR inhibitor lapatinib. (B) Immunohistochemical staining (reddish brown) of phospho-EGFR Tyr<sup>1086</sup>, phospho-Akt Ser<sup>473</sup>, and SREBP-1 before and after treatment with lapatinib from a representative patient (#1). Nuclei were counterstained with hematoxylin (blue). Inset shows nuclear SREBP-1 staining indicated by green arrow. Scale bar, 20  $\mu$ m. (C) Quantification of immunohistochemical staining from >1000 cells from at least five representative areas of each tumor before and

after lapatinib treatment;  $P$  values were determined by Wilcoxon test (7). Each diamond represents an individual patient. (D) Reduction of p-EGFR, p-Akt, and nuclear SREBP-1 staining for each GBM patient before (S1) and after (S2) treatment with lapatinib. (E) Correlation between inhibition of p-EGFR and inhibition of nuclear SREBP-1 staining. (F) Analysis of tumor tissue from nine GBM patients before and after treatment with rapamycin. (G) Immunohistochemical staining (reddish brown) of p-EGFR Tyr<sup>1086</sup>, p-Akt Ser<sup>473</sup>, SREBP-1, and p-S6 Ser<sup>235/236</sup> before and after treatment with rapamycin. transcriptional regulator of fatty acid synthesis. SREBP-1 undergoes N-terminal cleavage and nuclear translocation in response to cholesterol and fatty acid deprivation to initiate transcription of fatty acid synthetic genes (17, 18). Quantitative image analysis demonstrated a significant reduction in the percentage of nuclei staining positively for SREBP-1 between surgery 1 (before treatment) and surgery 2 (after treatment) in tumor specimens from lapatinib-treated patients (Fig. 1, B to D). This reduction in SREBP-1 nuclear staining was highly correlated with decreased p-EGFR immunostaining ( $R^2 = 0.73$ ,  $P < 0.00001$ ) (Fig. 1E). To provide confidence that the reduction in immunohistochemical nuclear staining for SREBP-1 was attributable to lapatinib, we made an identical set of measurements on tissue from 12 GBM patients from whom tumor tissue was available at baseline and at recurrence but who did not receive lapatinib (controls). No reduction in the percentage of nuclei staining positively for SREBP-1 between surgeries 1 and 2 was detected in these control GBM patients (fig. S1). Thus, inhibition of EGFR signaling resulted in significantly reduced nuclear SREBP-1 staining of tumor tissue from lapatinib-treated GBM patients. Consistent with a role for Akt in mediating EGFR-dependent nuclear translocation of SREBP-1, nuclear SREBP-1 staining was diminished when PTEN staining was apparent in p-EGFR-expressing tumors (fig. S2).

**Fig. 2.** Increased SREBP-1 cleavage and fatty acid accumulation in GBM cell lines correlates with abundant EGFR-PI3K-Akt signaling. (A) Western blot analysis of lysates from cell lines cultured in medium containing 1% FBS. For SREBP-1 immunoblot: P, precursor; N, cleaved N-terminal form.  $\alpha$ -Actin was used as loading control. (B) Biochemical analysis of effect of transfection of EGFRvIII or wild-type EGFR on SREBP-1 cleavage compared with that of parental U87 GBM cells that endogenously contain little EGFR and no EGFRvIII. Cell lines were cultured in serum-free media for 48 hours. (C) Total lipid extracts from U87 GBM cells, with or without EGFRvIII or EGFR overexpression, cultured in serum-free media for 48 hours were subjected to thin-layer chromatography and visualized by iodine.

### Rapamycin does not suppress SREBP-1 nuclear translocation in GBM patients

mTORC1 has been shown to mediate PI3K-Akt-dependent SREBP-1 cleavage to promote cell growth in vitro and in a *Drosophila* model (19). Therefore, we examined tumor tissue from a cohort of nine recurrent GBM patients treated with rapamycin in a Phase I/II clinical trial (14) (Fig. 1F). We previously demonstrated significant inhibition of phosphorylation of the mTORC1 target S6 in these patients ( $P < 0.05$ ) (Fig. 1, G and H) (14). However, mTORC1 inhibition did not correlate with reduced SREBP-1 nuclear staining (Fig. 1, G and H). Thus, in GBM patients, the amount of nuclear SREBP-1 staining was unaffected by rapamycin treatment at doses that inhibited mTORC1 signaling through S6.

### EGFR-PI3K-Akt signaling promotes SREBP-1 cleavage and increases fatty acid concentration in GBM cells

To assess the effect of EGFR signaling on SREBP-1 cleavage, we pharmacologically and genetically manipulated GBM cell lines at multiple nodes in the EGFR-PI3K-Akt signaling pathway. Substantially more cleaved SREBP-1 was detected in two of two cell lines with large amounts of p-EGFR (Fig. 2A, lanes 1 and 6) than in four of four cell lines with little p-EGFR (Fig. 2A, lanes 2 to 5); this did not appear to directly correlate with proliferation rate (fig. S3). The presence in U87 cells of a constitutively active EGFR allele, the EGFRvIII mutant, potently increased Akt phosphorylation and was sufficient to promote SREBP-1 cleavage, as well as increased concentrations of fatty acid (Fig. 2, B and C). EGF stimulation of GBM cells expressing wild-type EGFR elicited a dose- and time-dependent increase in SREBP-1 cleavage (Fig. 3, A and B), which was detectable 4 hours after EGF stimulation and was preceded by increased Akt Ser<sup>473</sup> and Thr<sup>308</sup> site phosphorylation (Fig. 3B). 25-Hydroxycholesterol (25-HC) (1  $\mu$ g/ml), an inhibitor of SREBP processing (18, 20–23), abrogated EGF-induced SREBP-1 cleavage (fig. S4). To determine whether increased SREBP-1 cleavage in response to EGF stimulation resulted in increased transcriptional regulation of the SREBP-1 transcriptional target fatty acid synthase (FAS), we performed chromatin immunoprecipitation (ChIP) analysis. SREBP-1 binding to the FAS promoter at the transcription start site (TSS) was increased 6.7 times ( $P < 0.02$ ) 4 hours after addition of EGF, whereas no increase in SREBP-1 binding to the FAS TSS was detected in vehicle-treated cells (Fig. 3, C and D). Furthermore, no SREBP-1 binding was detected to a site 200 base pairs (bp) upstream of the FAS TSS (Fig. 3, C and D). The EGFR inhibitor erlotinib, the PI3K inhibitor LY294002, and the Akt inhibitor Akti-1/2 all blocked EGF-stimulated SREBP-1 cleavage (Fig. 3E). U87-EGFRvIII cells lack PTEN; its introduction into cell line through retrovirus infection also abolished SREBP-1 cleavage (Fig. 3F). Rapamycin did not prevent EGFR-mediated SREBP-1 cleavage despite its inhibition of mTORC1 as assessed by the decrease in S6 phosphorylation (Fig. 3E, fig. S5), consistent with our findings in rapamycin-treated patients (Fig. 1, G and H). Thus, in GBM cells, EGFR signaling through PI3K-Akt promotes SREBP-1 cleavage, initiates binding of cleaved SREBP-1 to the FAS promoter, and increases intracellular fatty acid concentration in a process that does not depend on mTORC1 activity.

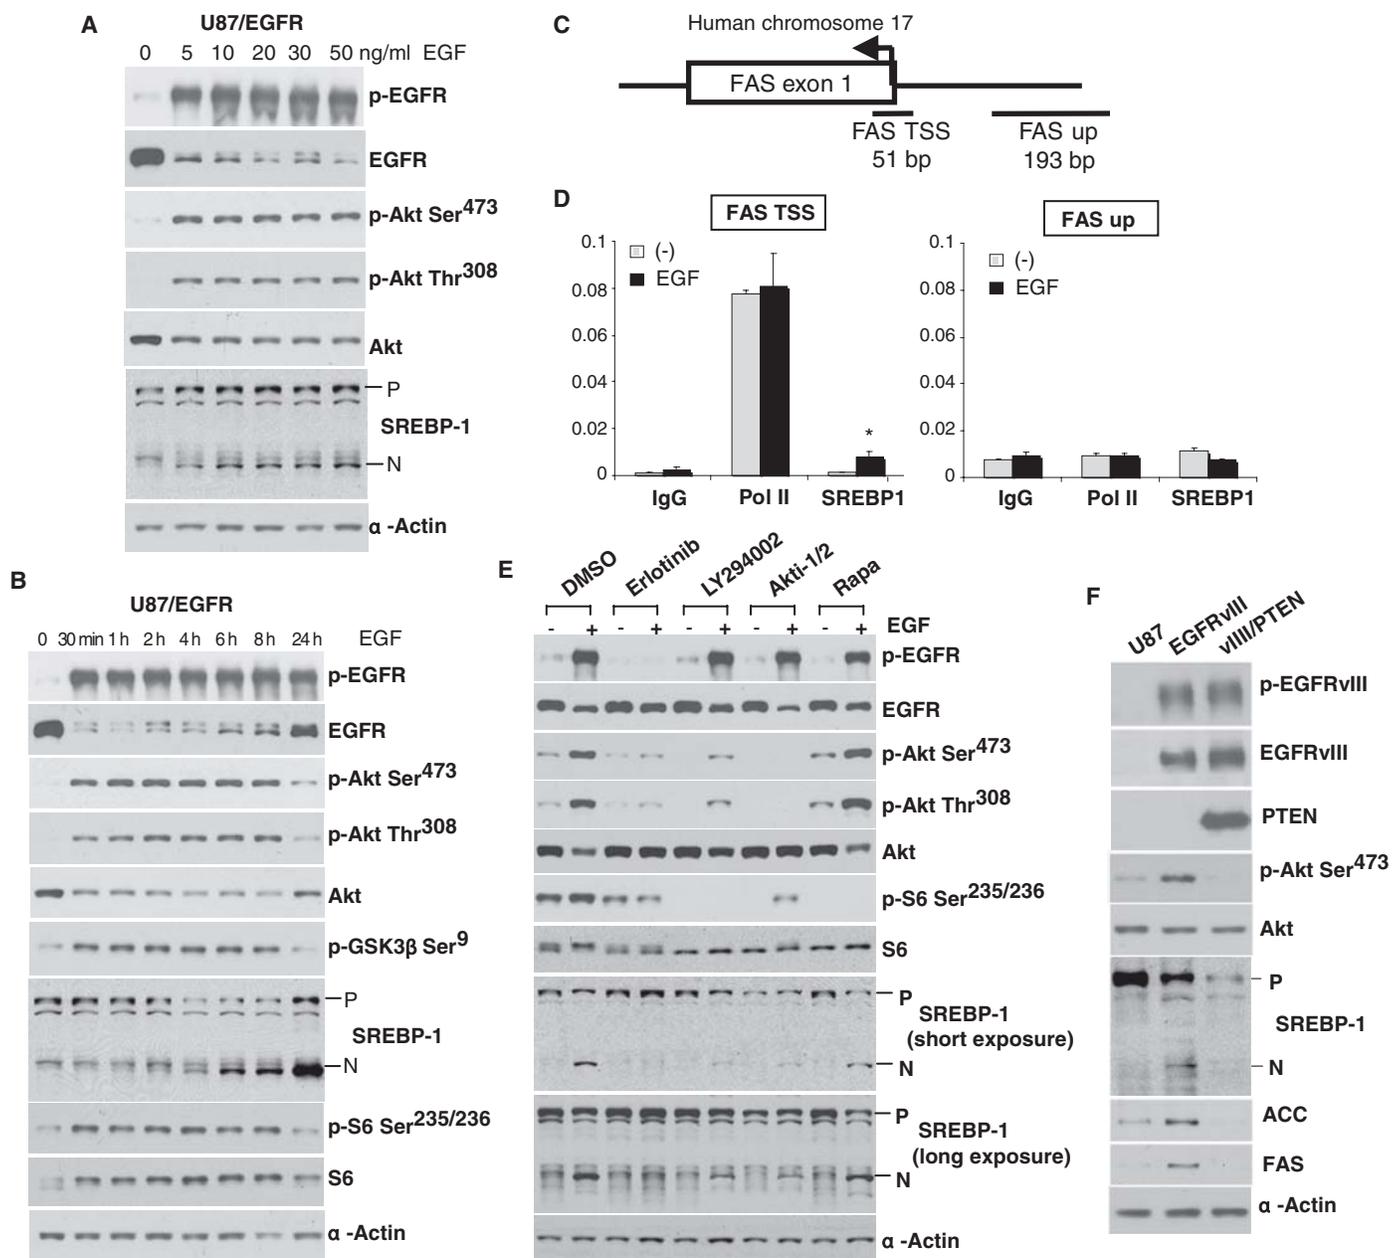

### Identification of molecular circuitry linking EGFR-Akt signaling with SREBP-1 in a large cohort of GBM patients

We examined the frequency with which we could detect p-EGFR, p-Akt, and nuclear SREBP-1, as well as acetyl coenzyme A (CoA) carboxylase (ACC) and FAS, two pivotal enzymes of the fatty acid synthetic pathway that are regulated by SREBP-1, in multiple representative regions of tumor and adjacent normal tissue from 140 patients with primary GBMs, that is, GBMs that had not transformed from lower-grade gliomas (Fig. 4A).

# RESEARCH ARTICLE

p-EGFR and p-Akt were detected in 44% and 77% of the tumor samples, respectively (table S2). This is consistent with the finding of EGFR mutation and/or amplification in 45% and PI3K-pathway activating mutations

in 87% of primary GBMs, respectively (3), suggesting that we had analyzed a representative patient population. Nuclear SREBP-1 and ACC and FAS staining were also significantly increased in tumor tissue relative

**Fig. 3.** Pharmacologic and genetic manipulation of GBM cells demonstrates that EGFR-PI3K-Akt signaling promotes SREBP-1 cleavage and binding to the FAS promoter (A). Effect of EGF dose and time course of EGF effect on SREBP-1 cleavage (B). U87-EGFR GBM cells were cultured in serum-free medium for 24 hours and treated for 6 hours with indicated concentration of EGF or with EGF (20 ng/ml) in time course experiments. Immunoblot analysis was performed with indicated antibodies. Antibodies against total proteins recognize both phosphorylated and nonphosphorylated proteins. upstream. (D) SREBP-1 abundance at the FAS TSS increases in response to EGF treatment. ChIP was performed on U87-EGFR cells with EGF (20 ng/ml) for 4 hours. Data are normalized against a fraction of the input gDNA, and each bar represents the mean  $\pm$  SEM of three independent biologic replicates. \* $P = 0.02$  relative to non-EGF-treated samples. (E) Effect of the EGFR inhibitor erlotinib (10  $\mu$ M), the PI3K inhibitor LY294002 (20  $\mu$ M), the Akt inhibitor Akti-1/2 (5  $\mu$ M), or the mTORC1 inhibitor rapamycin (1 nM) for 16 hours on SREBP-1 cleavage in U87-EGFR cells. DMSO, dimethyl sulfoxide. (F) Effect of PTEN reconstitution on EGFRvIII-mediated SREBP-1 cleavage and ACC and FAS abundance.

to normal brain ( $P < 0.0001$  for each) (table S2) and were highly correlated with each other ( $P < 0.0001$  for each comparison), with p-Akt ( $P < 0.0001$  for each), and with p-EGFR ( $P < 0.0001$  for each) (tables S3 and S4).

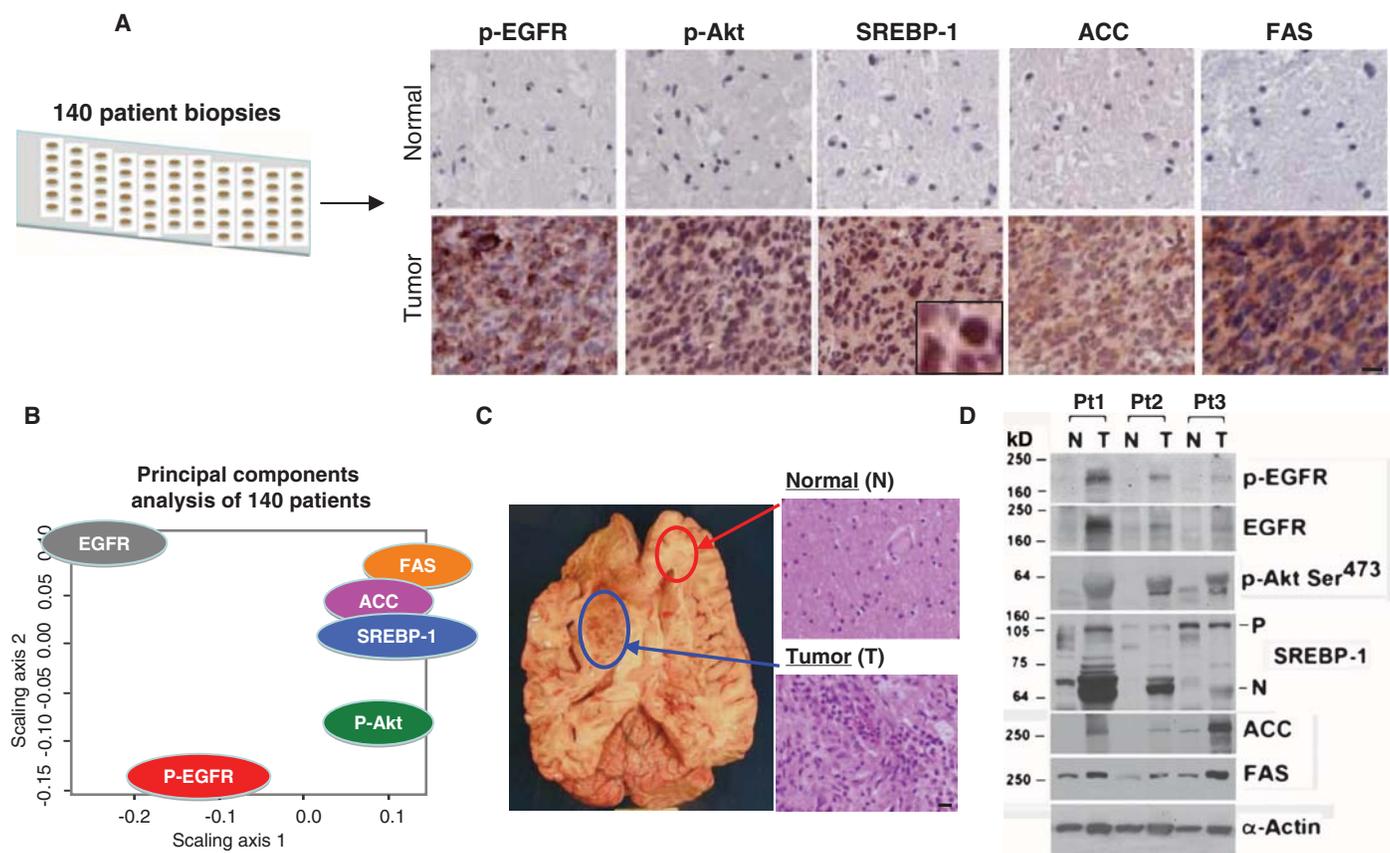

To determine if this data set might be used to uncover a signaling pathway linking EGFR signaling through PI3K-Akt to activation of SREBP-1 in patients, we used a classical multidimensional scaling (MDS) plot to visualize the pairwise correlations between p-EGFR, p-Akt, SREBP-1, ACC, and FAS (15, 24). MDS is an unsupervised data analysis method that does not assume previous knowledge about the interaction patterns between the proteins analyzed. The closer the distance between proteins in the MDS plot, the more correlated their expression in the 140 tumor samples. The MDS plot suggests a pattern of correlation between EGFR-Akt signaling and the SREBP-1-ACC-FAS fatty synthesis pathway (Fig. 4B) that is consistent with the preclinical observations (Fig. 3) and with the observations in the lapatinib-treated patients (Fig. 1). These results indicate that EGFR-Akt signaling is tightly correlated with SREBP-1, ACC, and FAS in clinical GBM samples.

Immunoblot analysis from autopsies of three GBM patients for whom tumor tissue and contralateral normal brain tissue were available demon-

strated increased SREBP-1 cleavage and ACC and FAS abundance in tumor tissue relative to normal brain, as well as increased EGFR and Akt phosphorylation (Fig. 4, C and D). Thus, in a representative cohort of GBM patients, p-EGFR was associated with increased p-Akt, nuclear SREBP-1 staining, and increased abundance of enzymes of the fatty acid biosynthetic pathway. Other RTKs that can activate Akt signaling, such as platelet-derived growth factor receptor (PDGFR) and mesenchymal-epithelial transition factor (MET), can also be found in GBM (9). Both p-PDGFR and p-MET correlated with SREBP-1 in GBM (fig. S6, table S4). Addition of hepatocyte growth factor to GBM cells carrying MET promoted SREBP-1 cleavage (fig. S6C), suggesting that other RTKs besides EGFR can also activate this pathway.

### Short hairpin RNA-mediated knockdown of SREBP-1 promotes cell death of EGFRvIII-bearing GBM cells

Having demonstrated that EGFR signaling through Akt can promote SREBP-1 cleavage and that EGFR and Akt phosphorylation correlates with SREBP-1 nuclear localization in tumors from GBM patients, we assessed the requirement for SREBP-1 in EGFR-activated cultured GBM cell line with a genetic approach. U87 and U87-EGFRvIII cells were in-

**Fig. 4.** p-EGFR is associated with p-Akt, nuclear SREBP-1 and increased abundance of ACC and FAS in a cohort of 140 GBM patients. (A) Analysis of p-EGFR, p-Akt, nuclear SREBP-1, and FAS and ACC abundance (reddish brown) in two TMAs comprising 252 tumor cores and 91 matched normal cores from 140 primary (de novo) GBM patients. The inset shows nuclear SREBP-1 staining. Images are magnified 20x; tissue is counterstained with hematoxylin. Scale bar, 20  $\mu$ m. (B) Multidimensional scaling

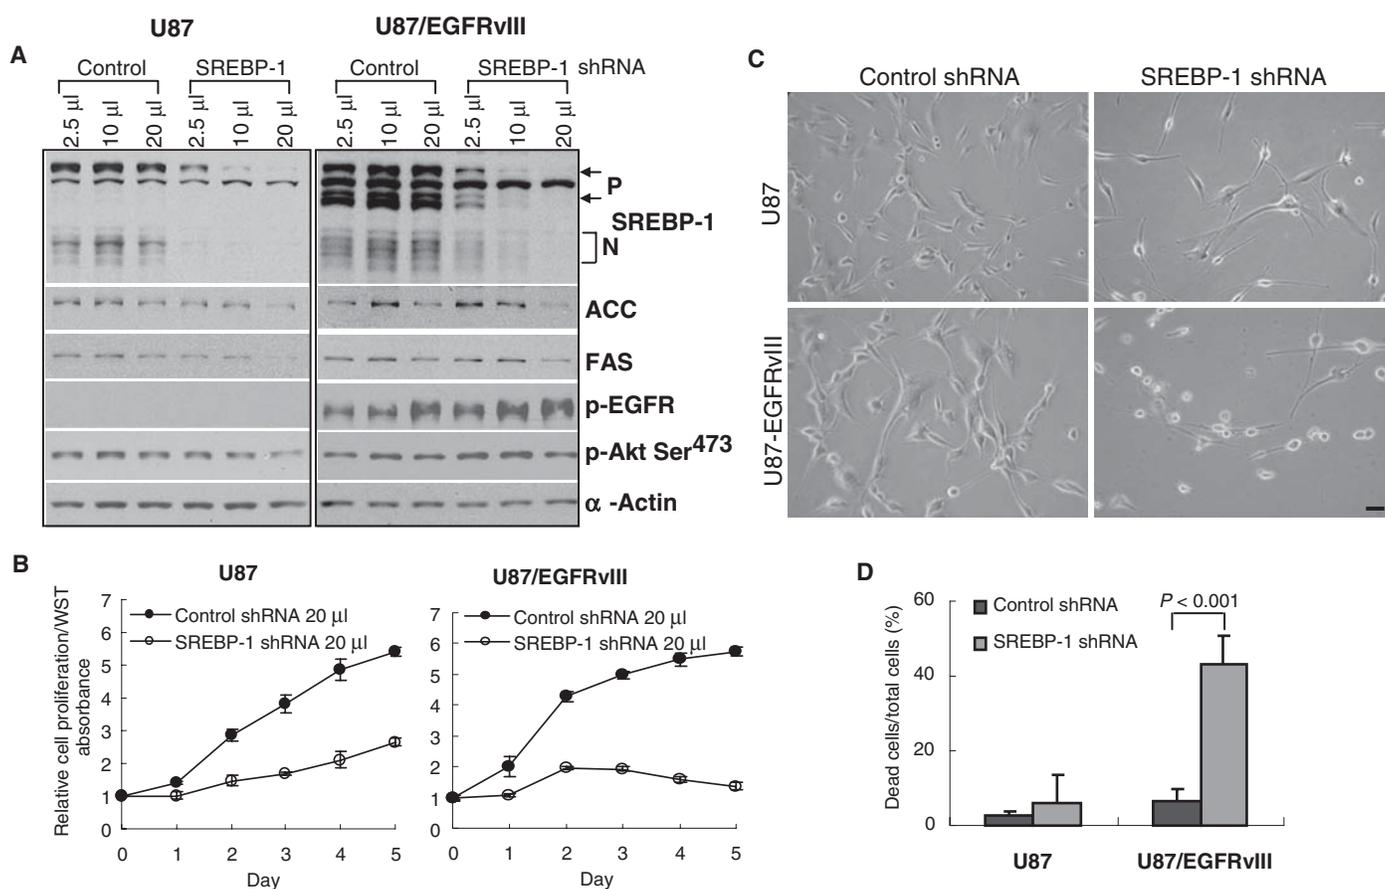

plot based on correlations among EGFR, p-EGFR Tyr<sup>1086</sup>, p-Akt Ser<sup>473</sup>, nuclear SREBP-1, ACC, and FAS. (C) Representative gross and microscopic pictures of tumor tissue (T) and contralateral normal brain tissue (N) from the brain of a GBM patient obtained at autopsy. Scale bar, 20  $\mu$ m. (D) Immunoblot analysis of p-EGFR, p-Akt, SREBP-1 cleavage, and ACC and FAS abundance in tumor (T) and contralateral normal brain tissue (N) from three GBM patients obtained at autopsy.

ected with an SREBP-1 short hairpin RNA (shRNA)-carrying lentivirus, or with a lentivirus carrying scrambled control shRNA, and the effect on downstream SREBP-1 targets and on cell proliferation and viability was measured (Fig. 5, A and B). SREBP-1 knockdown resulted in decreased abundance of ACC and FAS (Fig. 5A) and inhibition of cell proliferation (Fig. 5B), with slightly more inhibition of proliferation in U87-EGFRvIII cells than in U87 cells. However, genetic inhibition of SREBP-1 resulted in massive cell death in U87-EGFRvIII cells maintained in medium containing 1% fetal bovine serum (FBS) for 4 days, an effect that was not observed with parental U87 GBM cells (Fig. 5, C and D). Thus, EGFRvIII-bearing GBM cells demonstrated enhanced dependence on SREBP-1 for survival in low concentration of FBS.

### Inhibition of lipogenesis promotes EGFR-activated tumor cell death in vitro and in vivo

To assess the possible therapeutic consequences of pharmaceutical inhibition of the Akt-SREBP-1 pathway, and to determine whether its inhibition can promote the death of tumor cells with high degrees of EGFR signal-

ing, we treated a panel of GBM cell lines with 25-HC (1  $\mu\text{g}/\text{ml}$  for 3 days) (Fig. 6, A to C, and figs. S7 to S9). 25-HC caused massive cell death in tumors with large amounts of p-EGFR (Fig. 6B and figs. S7 to S9); minimal cell death was detected in GBM cell lines with little of p-EGFR (Fig. 6C and fig. S7A). Cell death in response to 25-HC (1  $\mu\text{g}/\text{ml}$  in 1% FBS for 3 days) was enhanced in U87-EGFRvIII cells relative to that in U87 cells (fig. S7C), an effect that was abrogated by PTEN (fig. S10). Thus, EGFR signaling through the PI3K pathway can sensitize GBM cells to the effects of 25-HC. To determine whether sensitivity to 25-HC depended on inhibition of cholesterol synthesis or of fatty acid synthesis, we treated GBM cells containing varying amounts of p-EGFR with the hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitor atorvastatin (1  $\mu\text{M}$ ) to inhibit cholesterol synthesis and the FAS inhibitor C75 (10  $\mu\text{g}/\text{ml}$ ) and to inhibit fatty acid production. Atorvastatin did not promote cell death, regardless of EGFR status (Fig. 6, B and C). In contrast, C75 caused cell death in cell lines with abundant p-EGFR but had significantly less effect on the cells with little p-EGFR (Fig. 6, B and C, and figs. S8 and S9). The apoptotic effect of C75 on cell lines with abundant p-EGFR was significantly rescued by

**Fig. 5.** shRNA knockdown of SREBP-1 promotes extensive tumor cell death of EGFRvIII-bearing GBM cells. (A) Immunoblot analysis demonstrating shRNA knockdown of SREBP-1 in U87 and U87-EGFRvIII GBM cells. SREBP-1 abundance was substantially reduced 48 hours after shRNA lentiviral infection. Cell lysates were analyzed by Western blot with the indicated antibodies. (B) Cells were infected with SREBP-1 shRNA lentivirus or scrambled control shRNA lentivirus for 24 hours, subcultured into 96-well plates,

and changed to 1% FBS medium after 24 hours. Relative cell proliferation was assayed daily until day 5 with the WST assay (Chemicon). (C and D) Cells were infected with SREBP-1 shRNA lentivirus or scrambled control for 24 hours, split into 12-well plates, and changed to 1% FBS medium for 4 days after 24 hours. Cell morphology was imaged by a phase-contrast inverted microscope and digital camera, and cell death was measured by trypan blue exclusion. Scale bar, 20  $\mu\text{m}$ .

addition of palmitate, an end product of FAS enzymatic activity (fig. S11). Thus, EGFR signaling markedly enhances demand for fatty acid synthesis necessary for the survival of GBM cells.

To determine whether constitutively active EGFR signaling was sufficient to impose enhanced dependence of GBM on lipogenesis *in vivo*, we implanted U87 and U87-EGFRvIII cells into opposite flanks of immunodeficient SCID/Beige mice (Fig. 6D). EGFRvIII-containing tumors grew significantly larger compared to tumors without EGFRvIII (Fig. 6, E and F), with increased Ki67 proliferation indices (fig. S12) and lower apoptotic indices (Fig. 6, G and H) (25). Atorvastatin did not inhibit tumor growth in either U87 or U87-EGFRvIII tumors (Fig. 6, E and F, and fig. S12). In contrast, C75 significantly inhibited tumor growth and

promoted apoptosis, showing greatly enhanced efficacy in EGFRvIII-bearing tumors compared to those without EGFRvIII (Fig. 6, E to H, and fig. S13). The effects of atorvastatin and C75 on tumor cell proliferation were modest (fig. S12). Atorvastatin augmented the apoptotic effect of C75 (Fig. 6, G and H). Therefore, a persistently active EGFR allele sensitized GBMs to apoptotic cell death in response to lipogenic inhibitors *in vitro* and *in vivo* (Fig. 7).

DISCUSSION

Our analysis of clinical samples from patients before and after treatment with lapatinib combined with our studies in cell lines and a mouse model

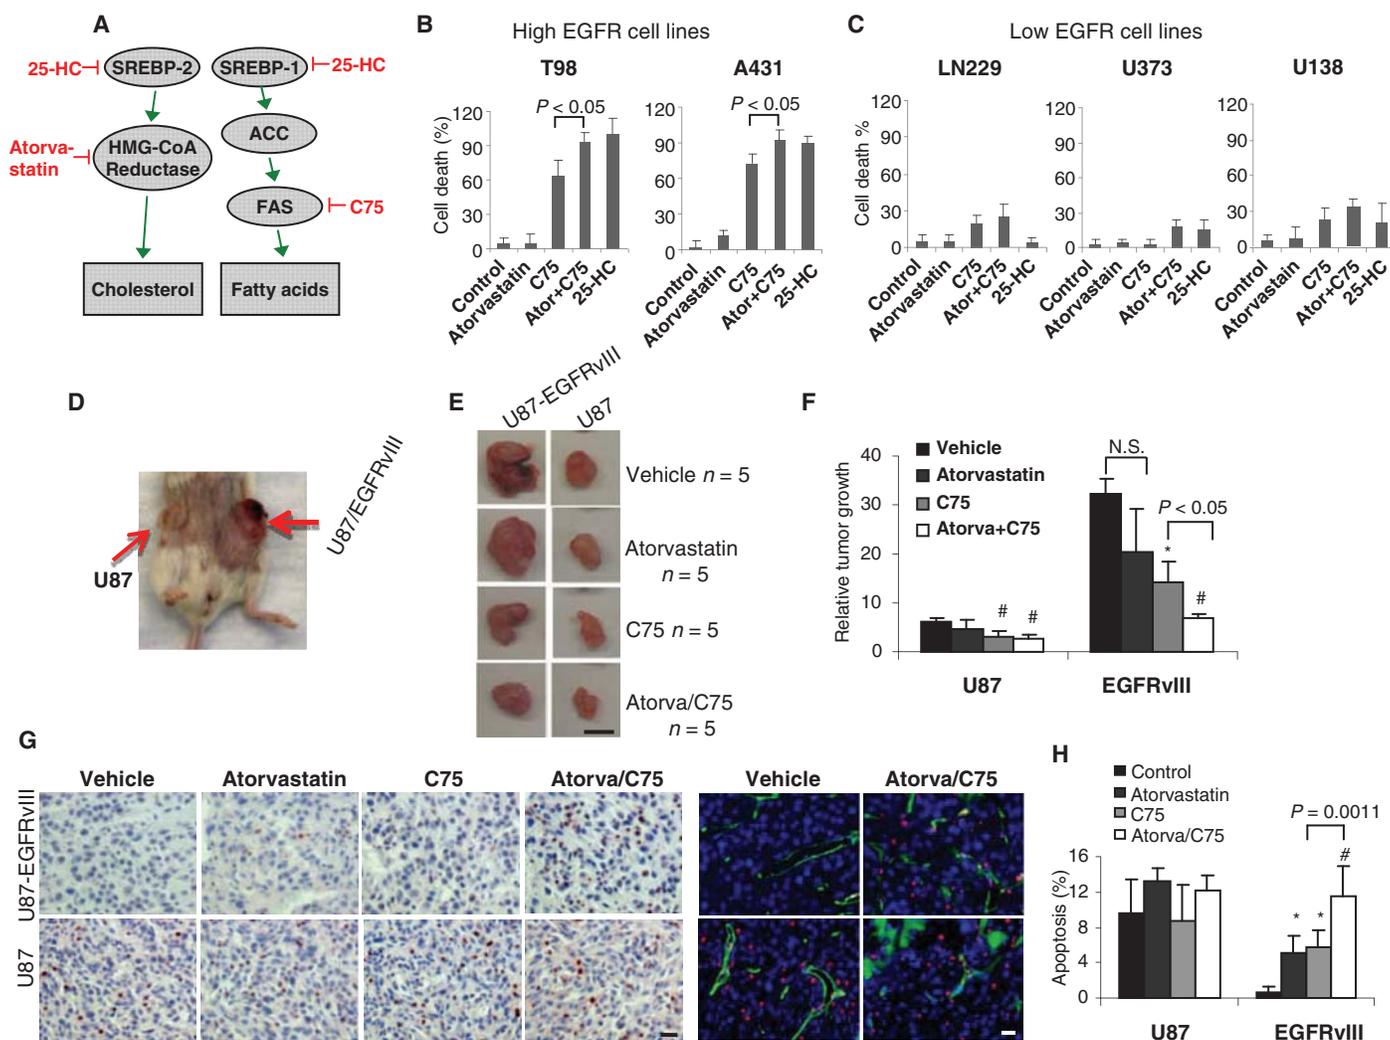

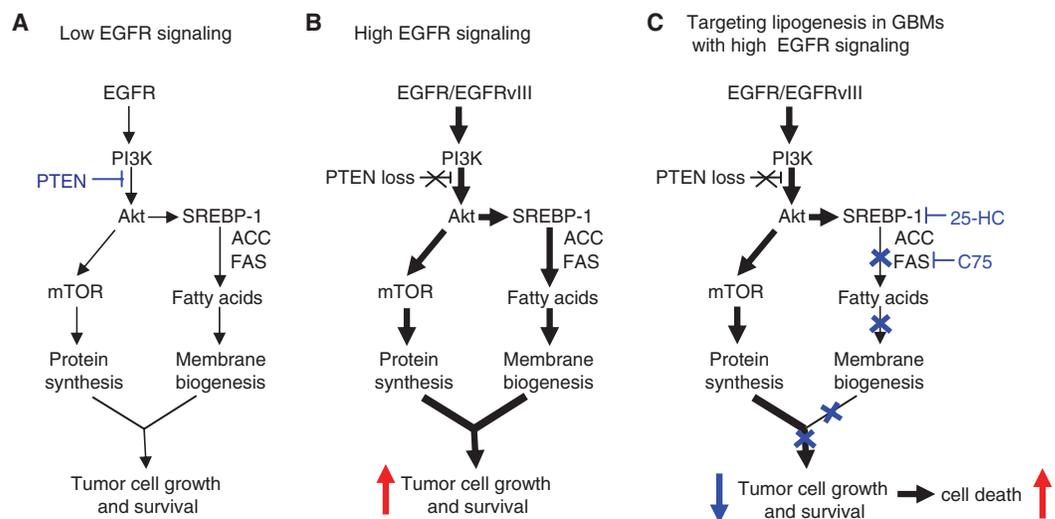

Fig. 6. A constitutively active form of the EGFR allele is sufficient to sensitize GBMs *in vitro* and *in vivo* to apoptotic cell death in response to FAS inhibition. **Fig. 7.** Model demonstrating the specific apoptotic effect of SREBP-1 and FAS inhibition on GBM cells bearing EGFRvIII. (A) In cells with little EGFR and intact PTEN, the demand for lipogenesis is modest and is balanced by low SREBP-1 pathway activation. (B) In GBM cells with abundant EGFR and PTEN loss, the SREBP-1-ACC-FAS pathway is up-regulated to meet the demand for increased fatty acid synthesis for membrane biogenesis of rapidly dividing cancer cells. (C) The SREBP-1 pathway becomes essential for survival in GBM cells bearing abundant EGFR or EGFRvIII. Targeting SREBP-1 or FAS is therefore lethal to EGFRvIII-bearing GBM cells or GBM cells with abundant EGFR signaling.

has enabled us to identify an EGFR- and Akt-dependent, rapamycin-insensitive signaling pathway that promotes GBM cell survival by bridging oncogenic growth factor receptor signaling with altered cellular metabolism (Fig. 7) (16, 26–29). Our data also support the recent demonstration that FAS suppresses tumor cell apoptosis in prostate cancer (30) and suggest a strategy for treating GBMs carrying constitutively activated EGFR, and possibly other cancers carrying activated EGFR, by targeting lipogenesis (31). Attempts to treat GBMs with constitutively active EGFR signaling by inhibiting EGFR itself have been limited because of resistance mediated by maintained signaling through the PI3K-Akt pathway (9, 14). It is not yet clear whether lapatinib will be subject to the same pitfalls; the first-phase analysis of the lapatinib clinical trial cannot answer that question. However, because fatty acid synthesis is downstream of EGFR-PI3K signaling, it is unlikely that rewiring of the pathway upstream, either through coactivation of other RTKs or by selection for loss of the tumor suppressor PTEN, will promote resistance to antilipogenic therapy. Increased EGFR signaling through PI3K-Akt enhances the requirement of GBM cells for fatty acid synthesis, possibly to provide sufficient lipids for membrane biogenesis in rapidly dividing tumor cells. This demand for increased fatty acids is met by EGFR-PI3K-Akt-mediated activation of SREBP-1 cleavage and up-regulation of ACC and FAS. Therefore, targeting SREBP-1, ACC, and FAS is lethal to GBM cells with abundant EGFR signaling but spares cells with little EGFR signaling, including normal cells (Fig. 7). These results define a therapeutically exploitable synthetic lethal interaction (32); that is, SREBP-1-ACC-FAS becomes essential for survival when EGFR is constitutively activated, explaining the specificity of the effect of C75 on EGFRvIII-bearing tumors. It will be important to determine whether targeting fatty acid synthesis results in more effective therapy for GBM patients and potentially other cancer patients with EGFR-dependent tumors.

## MATERIALS AND METHODS

### Phase II lapatinib clinical trial

North American Brain Tumor Consortium (NABTC) trial 04-01 titled “A biomarker and Phase II study of GW 572016 (lapatinib) in recurrent malignant glioma” enrolled consented patients from University of California at

Los Angeles (UCLA), University of California at San Francisco, Dana-Farber Cancer Center, Memorial Sloan Kettering Cancer Center, University of Pittsburgh, Neuro-oncology branch of National Institutes of Health, University of Wisconsin, and Duke University. Adult patients who had a Karnofsky performance score (KPS) equal to or greater than 60, who were not on enzyme-inducing antiepileptic agents and who had normal hematologic, metabolic, and cardiac function were eligible for this study. In addition, patients must have been candidates for surgical re-resection at the time of enrollment. Patients were administered 750 mg of lapatinib orally twice a day (BID) for 7 to 10 days (depending on whether treatment interval fell over a weekend) before surgery, the time to steady state. Blood and tissue samples were obtained at the time of resection. After recovery from surgery, patients resumed lapatinib treatment at the neoadjuvant dose of 750 mg BID until clinical or radiographic evidence for tumor progression was found. A complete description of the clinical trial results will be reported separately. The first cohort of patients for whom tissue was available before and after lapatinib ( $n = 9$ ) were included in this study.

### Lapatinib concentration in peripheral blood and tumor tissue

Blood and tissue samples (minimum 50 mg) were obtained at time of resection. Lapatinib concentrations were determined by liquid chromatography-electrospray ionization tandem mass spectrometry (33), with a lower limit of detection of 5 ng/ml in plasma and 0.08 ng/ml in brain tumor tissue extracts.

### Phase I/II rapamycin clinical trial

The clinical trial protocol (#02-03-078-11) was approved by the institutional review board of the UCLA. Enrollment was restricted to patients with a histological diagnosis of GBM, radiographic evidence for disease recurrence after standard GBM therapy (surgery, radiation, temozolamide), evidence for PTEN loss in tumor tissue, and no previous mTOR inhibitor therapy. Other enrollment criteria included age >18 years, KPS  $\geq 60$ , life expectancy  $\geq 8$  weeks, and normal hematologic and metabolic function; in addition, limitations were placed on baseline concentrations of plasma cholesterol and triglycerides. Irradiation and chemotherapy were discontinued for  $\geq 4$  weeks before trial entry ( $\geq 6$  weeks if previous therapy included a nitrosourea compound). All 15 patients enrolled in the clinical trial gave written informed consent to participate in these evaluations.

Fifteen patients with PTEN-deficient tumors, who also met all other eligibility criteria, were enrolled at the time of tumor recurrence and received neoadjuvant oral daily rapamycin (2, 5, or 10 mg per day) for about 1 week (median, 6 days; mean, 7.5 days) before salvage surgical resection (S2). After recovery from surgery, patients resumed daily rapamycin treatment at the neoadjuvant dose until clinical or radiographic evidence for tumor progression was found. Details regarding the results from this trial are published in Cloughesy *et al.* (14). Pre- and posttreatment tissue samples from nine patients were available for analysis in this study.

### Cell lines

U87 and U87-EGFRvIII, U87-EGFR, U87-EGFRvIII-PTEN isogenic GBM cell lines, A431 epidermoid carcinoma cell line, and LN229, T98, U138, and U373 GBM cell lines were cultured in Dulbecco's modified Eagle's medium (Cellgro) supplemented with 10% FBS (Omega Scientific) in a humidified atmosphere of 5% CO<sub>2</sub> and 95% air at 37°C. U87-EGFRvIII cells were a gift of W. Cavenee. U87-EGFRvIII-PTEN cells were generated by plasmid-mediated transfection of PTEN into U87-EGFRvIII cells followed by selection for stable clones. U87-EGFR cells were generated by retrovirus-mediated transduction of wild-type EGFR into U87 cells followed by selection of stable clones. These cell lines have previously been reported (7). H1975 non-small cell lung carcinoma cell line was cultured in RPMI 1640 with 10% FBS.

### Antibodies and reagents

We used antibodies directed against the following: ACC, FAS, p-Akt Ser<sup>473</sup>, p-Akt Thr<sup>308</sup>, Akt, p-S6<sup>Ser235/236</sup>, p-Met Tyr<sup>1234</sup>, p-PDGFR Tyr<sup>1021</sup>, p-GSK3beta Ser<sup>9</sup>, PTEN (Cell Signaling);  $\alpha$ -actin (Sigma); SREBP-1 (BD Pharmingen); p-Met Tyr<sup>1349</sup>, p-PDGFR Tyr<sup>579</sup> (Abgent); EGFR/EGFRvIII cocktail antibody (Upstate); phospho-EGFR Tyr<sup>1086</sup> (Invitrogen); CD31 (Abcam); PTEN (6H2.1, Cascade BioScience, IHC). Reagents used are LY294002 and 25-HC, C75, rapamycin, palmitate, polybrene (Sigma), erlotinib (ChemieTex), Akti-1/2 (Calbiochem), and atorvastatin (Toronto Research Chemicals).

### Cell proliferation and death assays

Cells were seeded in 96 wells and were treated after 24 hours with different drugs indicated in each experiment in medium containing 1% FBS. Relative proliferation to control cells with vehicle treatment was checked with a Cell Proliferation Assay Kit (Chemicon). Cells were incubated 1.5 hours after addition of tetrazolium salt WST-1 [2-(4-iodophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfo-phenyl)-2H-tetrazolium, monosodium salt] (Chemicon) at 5% CO<sub>2</sub> and 37°C, and the absorbance of the treated and untreated cells was measured with a microplate reader (Bio-Rad) at 420 to 480 nm. Cell death was assessed by trypan blue exclusion (Invitrogen).

### shRNA assay

Cells ( $5 \times 10^4$ ) were seeded in 12-well plates and maintained for 24 hours, after which the medium was replaced with fresh 5% FBS medium including polybrene (5  $\mu$ g/ml; Sigma), and then shRNA lentivirus was added to cells followed by incubation for 24 hours. For Western blot analysis, infected cells were incubated in fresh 5% FBS medium for another 24 hours, then lysed. For cell proliferation or cell death assays, infected cells were subcultured into 96-well plates or 12-well plates, maintained in 5% FBS medium for 24 hours, and then changed to 1% FBS medium and maintained for 4 to 5 days.

### Western blotting

Western blotting was as previously described (34). Cultured cells or snap-frozen tissue samples were lysed and homogenized with a buffer containing

tris (10 mmol/liter; pH 7.4), NaCl (100 mmol/liter), EDTA (1 mmol/liter), EGTA (1 mmol/liter), NaF (1 mmol/liter), Na<sub>4</sub>P<sub>2</sub>O<sub>7</sub> (20 mmol/liter), Na<sub>3</sub>VO<sub>4</sub> (2 mmol/liter), 0.1% sodium dodecyl sulfate, 0.5% sodium deoxycholate, 1% Triton X-100, 10% glycerol, leupeptin (10  $\mu$ g/ml), aprotinin (60  $\mu$ g/ml), and phenylmethanesulfonyl fluoride (1 mmol/liter). Equal amounts of protein extracts were separated by 8 or 10% SDS-polyacrylamide gel electrophoresis and then transferred to a polyvinylidene difluoride membrane (Bio-Rad Laboratories). The membrane was blocked for 1 hour in tris-buffered saline containing 0.1% Tween 20 and 5% nonfat milk and then probed with various primary antibodies, followed by secondary antibodies conjugated to horseradish peroxidase (HRP). The immunoreactivity was revealed by use of an ECL kit (Amersham Biosciences).

### Thin-layer chromatography for lipids

Cellular total lipid extract was obtained by scraping cells from the 10-cm culture dish into 2 ml of phosphate-buffered saline (PBS)-containing protease inhibitor and 1 mM phenylmethylsulfonyl fluoride and adding 4 ml of chloroform/methanol (2:1, v/v) with 0.01% butylated hydroxytoluene (Sigma). The solution was vortexed and centrifuged at 1500g for 5 min. The organic phase was collected, and 2.5 ml of chloroform was added to the residual aqueous phase which was vortexed and centrifuged at 1500g for 5 min. The organic phase was pooled with the previous extraction. Thin-layer chromatography was performed by spotting the cellular total lipid extract on a 5 cm by 10 cm silica gel aluminum sheet (EMD Chemicals) and developing with hexane/diethyl ether/acetic acid (80:20:2, v/v/v). Lipids were visualized with iodine vapor and imaged with a desktop scanner (31, 35).

### Immunohistochemical and immunofluorescent staining

Paraffin-embedded tissue blocks were sectioned using the UCLA Pathology Histology and Tissue Core Facility. Immunohistochemical staining was performed as previously described (7). Slides were counterstained with hematoxylin to visualize nuclei. Paraffin-embedded tissue sections underwent immunohistochemical analysis in which the results were scored independently by two pathologists who were unaware of the findings of the molecular analyses. Quantitative image analysis to confirm the pathologists' scoring was also performed with Soft Imaging System software (15). We have previously demonstrated the utility of this quantitative method for measuring drug-specific effects in paraffin-embedded tissue samples from GBM patients enrolled in clinical trials with targeted agents (7, 14).

### Tissue microarrays

Tissue microarrays (TMAs) were used to analyze p-EGFR Tyr<sup>1086</sup>, p-Akt Ser<sup>473</sup>, nuclear SREBP-1, ACC, and FAS immunohistochemical staining in 140 GBM patient samples. TMAs enable tumor tissue samples from hundreds of patients to be analyzed on the same histologic slide. We constructed two GBM TMAs by with a 0.6-mm needle to extract 252 representative tumor tissue cores and 91 adjacent normal brain tissue cores from the paraffin-embedded tissue blocks of 140 primary GBM patients. These cores were placed in a grid pattern into two recipient paraffin blocks, from which tissue sections were cut for immunohistochemical analysis of p-EGFR, p-Akt, nuclear SREBP-1, ACC, and FAS. These TMAs have been used for other studies (15, 36).

### TUNEL staining

Paraffin sections were deparaffinized and subjected to graded rehydration as with the immunohistochemical method. Peroxidase activity was quenched with 3% hydrogen peroxide in water. Terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick end labeling (TUNEL) staining was performed with digoxigenin-conjugated deoxyuridine triphosphate and HRP-conjugated antibodies against digoxigenin following the manufacturer's

protocol (Roche). Visualization for staining was performed with NovaRed substrate (Vector Laboratories), and tissues were then counterstained with hematoxylin.

For TUNEL immunofluorescence staining, tissue sections were stained for apoptosis with the In Situ Cell Death Detection Kit, TMR red, and following the manufacturer's protocol (Roche). Nuclei are stained blue by 4',6-diamidino-2-phenylindole (DAPI); CD31 positive blood vessels are stained green.

### ChIP assay

ChIP assays were performed on U87-EGFR cells with or without 4 hours of EGF treatment (20 ng/ml). Cells in two 15-cm plates were pooled for each replicate. ChIP was performed essentially as described (37). Briefly, cells were cross-linked for 5 min in 1% formaldehyde in PBS. After extensive sonication (10 min total sonication time in 30-s pulses), preclearing with protein G–Sepharose, and removal of a 50- $\mu$ l (1/20 input) fraction for normalization, soluble chromatin from each replicate was split three ways for overnight immunoprecipitations with 2  $\mu$ g of the following antibodies: mouse immunoglobulin G (Millipore cat #12-371, nonspecific control), antibody against polymerase II (Millipore clone CTD4H8, cat #05-623, positive control), or antibody against SREBP-1 (clone 2A4 derived from American Type Culture Collection hybridoma cat #CRL-2121). DNA-protein complexes were pulled down by incubation for 2 hours with protein G–Sepharose, washed, and processed as previously described. Genomic DNA (gDNA) was assayed by quantitative polymerase chain reaction (qPCR) with primers amplifying the FAS TSS and a fragment upstream of the TSS. qPCR values were normalized against the input gDNA content for each replicate. qPCR primers are FAS TSS forward, CTCTTGGCTCCCTCTAGGC; FAS TSS reverse, GATGGCCGCGGTT-TAAATA; FAS up forward, GTGGGGCTGGGACTGAG; and FAS up reverse, CAGTGTGGCCCAAGCATT.

### Xenograft model

Isogenic human U87 malignant glioma cells (U87, U87-EGFRvIII) were implanted into immunodeficient SCID/Beige mice for subcutaneous xenograft studies. SCID/Beige mice were bred and kept under defined-flora pathogen-free conditions at the Association for Assessment of Laboratory Animal Care–approved Animal Facility of the Division of Experimental Radiation Oncology, UCLA. For subcutaneous implantation, exponentially growing tumor cells in culture were trypsinized, enumerated by trypan blue exclusion, and resuspended at  $1 \times 10^6$  cells/ml in a solution of Dulbecco's phosphate-buffered saline (dPBS) and Matrigel (BD Biosciences). Tumor growth was monitored with calipers by measuring the perpendicular diameter of each subcutaneous tumor. U87 and U87-EGFRvIII cell lines were implanted subcutaneously on opposite sides of the mouse abdomen ( $n = 20$ ) for treatment with atorvastatin (10 mg/kg daily; Toronto Research Chemicals) and C75 (30 mg/kg weekly; Sigma) alone or in combination. Mice were euthanized if tumors reached 14 mm in maximum diameter or animals showed signs of illness. All experiments were conducted after approval by the Chancellor's Animal Research Committee of UCLA.

### Immunohistochemistry and image analysis–based scoring

Tissue sections were cut from blocks of formalin-fixed paraffin tumor tissue from GBM patients treated with lapatinib or rapamycin. Tumor specimens were obtained according to a protocol approved by the institutional review board of UCLA. The first set of paired pre- and posttreatment tumor tissues ( $n = 9$ ) for lapatinib trial and nine pairs of pre- and posttreatment tumor tissues for the rapamycin trial were examined. The control group included 12 patient tumor tissues. Tissue sections (5  $\mu$ m) were stained with polyclonal antibodies directed against p-EGFR Tyr<sup>1086</sup>, p-Met Tyr<sup>1349</sup>,

p-PDGFR Tyr<sup>579</sup>, p-Akt Ser<sup>473</sup>, SREBP-1, ACC, and FAS for sections of lapatinib trial and TMA, and p-EGFR, p-Akt, SREBP-1, and p-S6 Ser<sup>235/236</sup> for sections of rapamycin trial. Digital scores for p-EGFR, p-Akt, and p-S6 were based on absolute staining intensity of tumor cells as quantified after false-color conversion. Sections were photographed with a Colorview II camera mounted on an Olympus BX41 microscope at 20 $\times$  magnification. Five images were captured per slide from representative regions of the tumor. Borders between individual cells were approximated with a separator function of the Soft Imaging Software (with the parameters of smooth and fine/coarse, 2 and 10, respectively). Quantitative analysis was done with HSI color algorithm on the basis of hue, saturation, and intensity. Saturations of the separated cell in the images were quantified in the red-brown hue range to exclude the negative staining area with hematoxylin nuclear staining. To compare the staining intensity of all slides, mean saturation of total cells on each image was quantified and calculated; 1500 to 2000 cells per case (on average) were measured for each slide, and statistical comparisons were performed with the R software, using a previously described approach (14). For scoring of SREBP-1 staining, separated cells were quantified with red brown hue range (cells with positive nuclear staining) and total hue range (all cells) after cell border separation, and the proportion of positive cells was calculated on the basis of these numbers.

### Statistical analysis

Results are shown as mean  $\pm$  SEM. Fisher's exact test was used to assess correlations between various molecular markers. Other comparisons in cell growth assays, tumor volumes, tumor metabolism, and cell death were performed with a two-tailed *t* test, as well as by analysis of variance, as appropriate. We used Wilcoxon test to determine the *P* value for staining of lapatinib trial pre- and posttreatment tissue samples. *P* < 0.05 was considered as statistically significant. The computation of the Pearson correlations and the logistic regression analysis were all carried out with the R software. To depict the relationship between the variables, we used the R function CMD scale to arrive at a two-dimensional classical MDS plot. We also followed the convention of path analysis to represent a causal model by a directed graph and used partial correlation testing to fit a causal model.
